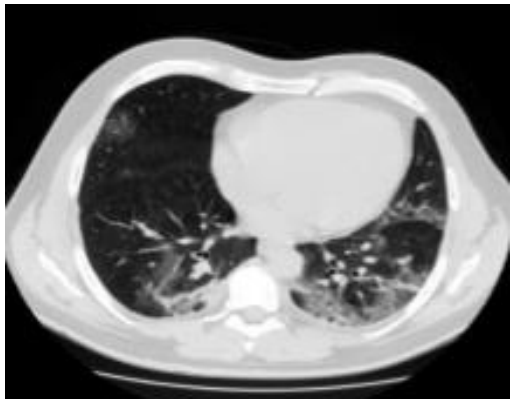
COVID-19 pneumonia: ARDS or not?

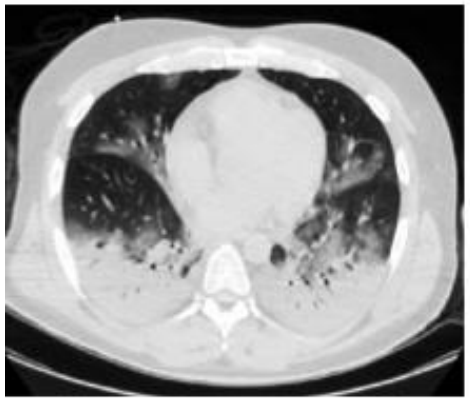
Luciano Gattinoni[1*], Davide Chiumello[2] and Sandra Rossi[3]



Type 1: Near normal pulmonary compliance with isolated viral pneumonia

In these patients, severe hypoxemia is associated with respiratory system compliance > 50 ml/cmH_2O. The lung's gas volume is high, the recruitability is minimal, and the hypoxemia is likely due to the loss of hypoxic pulmonary vasoconstriction and impaired regulation of pulmonary blood flow. Therefore, severe hypoxemia is primarily due to ventilation/perfusion (V_A/Q) mismatch. High PEEP and prone positioning do not improve oxygenation through recruitment of collapsed areas, but redistribute pulmonary perfusion, improving the V_A/Q relationship. Lung CT scans in those patients confirm that there are no significant areas to recruit, but the right-to-left venous admixture is typically around 50%.

SILI ?



Type 2: Decreased pulmonary compliance

In 20–30% of these COVID-19 patients admitted to the intensive care unit (ICU), severe hypoxemia is associated with compliance values < 40 ml/cmH_2O, indicating severe ARDS [3]. It is certainly possible that their lower compliance (i.e., lower gas volume and increased recruitability) is due to the natural evolution of the disease, but we cannot exclude the possibility that this severity of damage (increased edema) results in part from the initial respiratory management. Indeed, some of these hypoxemic patients receive CPAP or non-invasive ventilation before ICU admission and present with very high respiratory drives, vigorous inspiratory efforts, and highly negative intrathoracic pressures. Therefore, in addition to viral pneumonia, those patients likely have self-inflicted ventilator-induced lung injury [4].

Respiratory physiology of COVID-19-induced respiratory failure compared to ARDS of other etiologies

Early after establishment of mechanical ventilation, pts with COVID-19 show a conventional ARDS phenotype, with heterogeneity in respiratory mechanics, aeration loss related to the degree of hypoxemia, and inter-individually variable recruitability.

Physiological differences between COVID-19 pts and ARDS from other etiologies appear clinically negligible.

Until other data emerge, **clinicians treating COVID-19 patients should adhere to most recent guidelines regarding ARDS management**

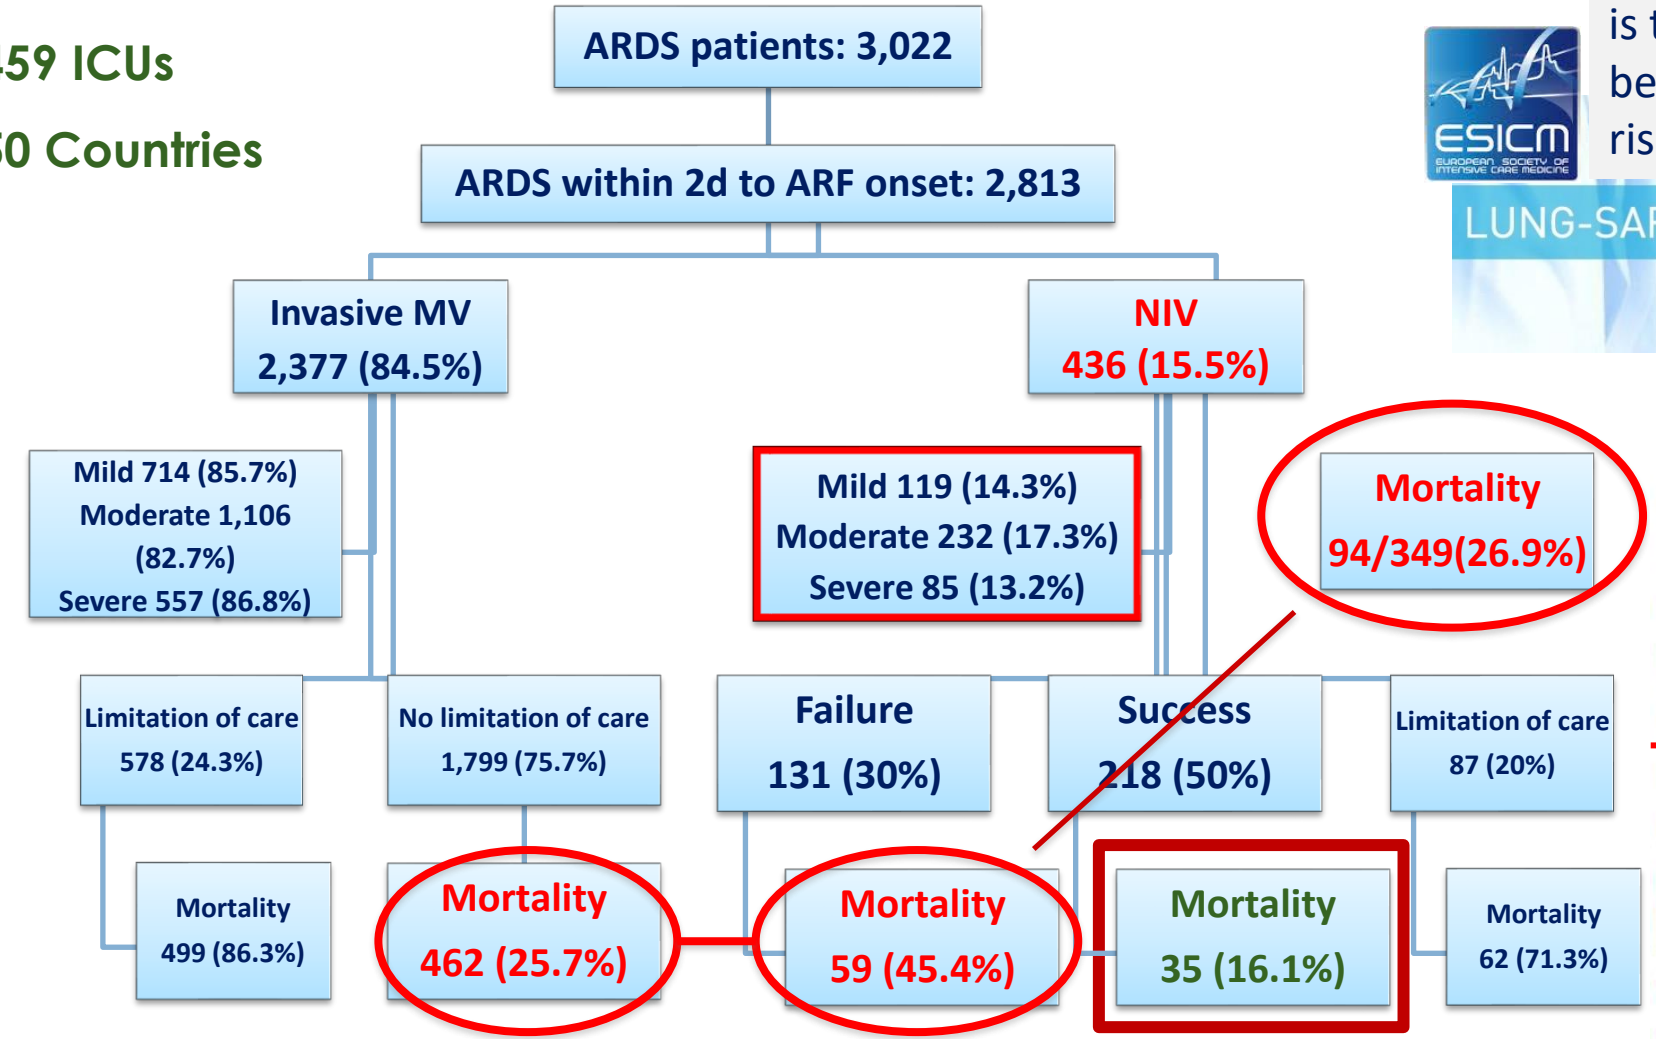
NIV IN PATIENTS WITH ARDS: THE LUNG-SAFE ANALYSIS

459 ICUs

50 Countries

NIV as a first-line strategy in pts with AHRF is the balance between the potential benefits of avoiding intubation and the risks deriving from SILI.



In conclusion, in a large cohort of patients with ARDS, NIV was used in 15% of cases, and was used to a similar extent across the severity categories. NIV failure occurred in more than one-third of patients with ARDS and in almost half of patients with moderate and severe ARDS. Mortality rates in patients that failed NIV were high. Of concern, NIV was associated with a worse adjusted ICU mortality than invasive-MV in patients with a Pa_{O_2}/FI_{O_2} lower than 150 mm Hg.

DOI: 10.1056/NEJMra2204556

ACUTE RESPIRATORY FAILURE IS A COMMON INDICATION FOR ADMISSION to an intensive care unit. Invasive mechanical ventilation, particularly positive-pressure ventilation, has been the cornerstone of the management of severe forms of acute respiratory failure since the 1950s.[1] However, despite major advancements in critical care management, the complications and mortality associated with intubation and positive-pressure ventilation are not insignificant.[2] Efforts to circumvent invasive mechanical ventilation through the use of noninvasive devices have therefore garnered much attention. For some conditions, such as cardiogenic pulmonary edema and chronic obstructive pulmonary disease (COPD) exacerbations, noninvasive respiratory support is highly beneficial,[3] whereas for hypoxemic respiratory failure, the presence of associated conditions such as sepsis and shock[4] may make the use of noninvasive respiratory support risky and its benefits more difficult to delineate.

Three main methods of noninvasive support are used in the acute care setting: a high flow of gas delivered through a large-bore nonocclusive nasal cannula (i.e., high-flow nasal cannula), continuous positive airway pressure (CPAP), and noninvasive ventilation (i.e., pressure-support ventilation with positive end-expiratory pressure [PEEP]). In this review, we provide an overview of the physiological effects, different configurations, clinical indications, and evidence for the use of noninvasive respiratory support in adults with acute respiratory failure.

Abstract

Spontaneous respiratory effort during mechanical ventilation has long been recognized to improve oxygenation, and because oxygenation is a key management target, such effort may seem beneficial. Also, disuse and loss of peripheral muscle and diaphragm function is increasingly recognized, and thus spontaneous breathing may confer additional advantage. Reflecting this, epidemiologic data suggest that the use of partial (vs. full) support modes of ventilation is increasing.

Notwithstanding the central place of spontaneous breathing in mechanical ventilation, accumulating evidence indicates that it may cause—or worsen—acute lung injury, especially if acute respiratory distress syndrome is severe and spontaneous effort is vigorous. This Perspective reviews the evidence for this phenomenon, explores mechanisms of injury, and provides suggestions for clinical management and future research.

Keywords: mechanical ventilation; acute respiratory distress syndrome; spontaneous breathing; ventilator-induced lung injury

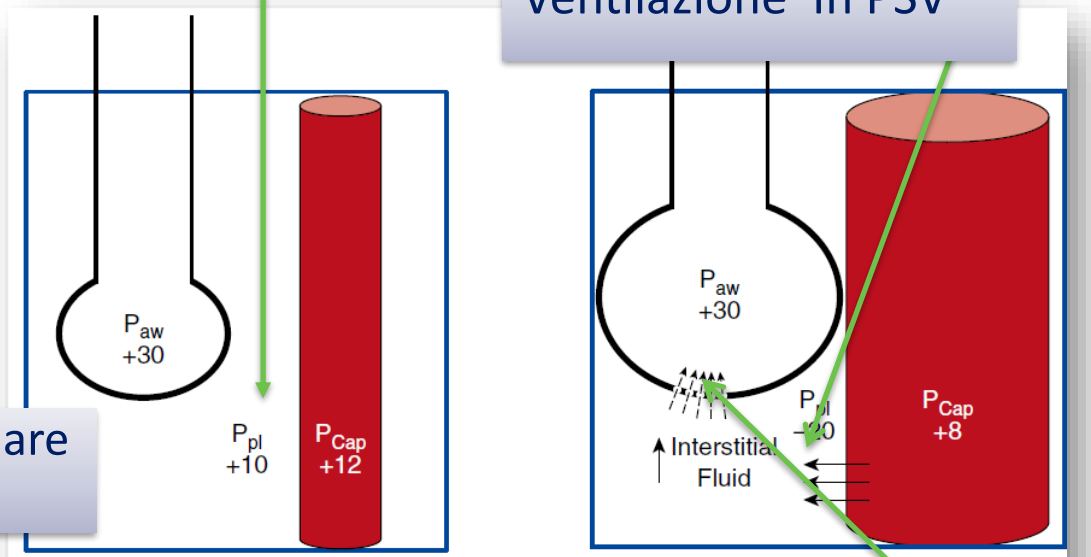

Figure 1. Spontaneous effort and transpulmonary and transvascular pressures. During a mechanical breath (*left*), the transpulmonary pressure (Paw – Ppl = P_L) distending the lung is +20 (30 – 10); the pulmonary blood vessels are compressed by the positive-pressure breath and the transvascular pressure (Pcap – Ppl) is low (assume 12 – 10 = 2). When spontaneous effort is added (*right*), the P_L (30 + 20 = +50) is greater, thereby increasing the V_T and causing lung injury. In addition, the negative Ppl (−20) distends the pulmonary blood vessels and increases perfusion; the transvascular pressure is greater (assume 8 – −20 = +28), increasing fluid shift to the interstitium. In the presence of injury, permeability (and therefore propensity to alveolar edema) is increased. Paw = airway pressure; Pcap = capillary hydrostatic pressure; Ppl = pleural pressure.

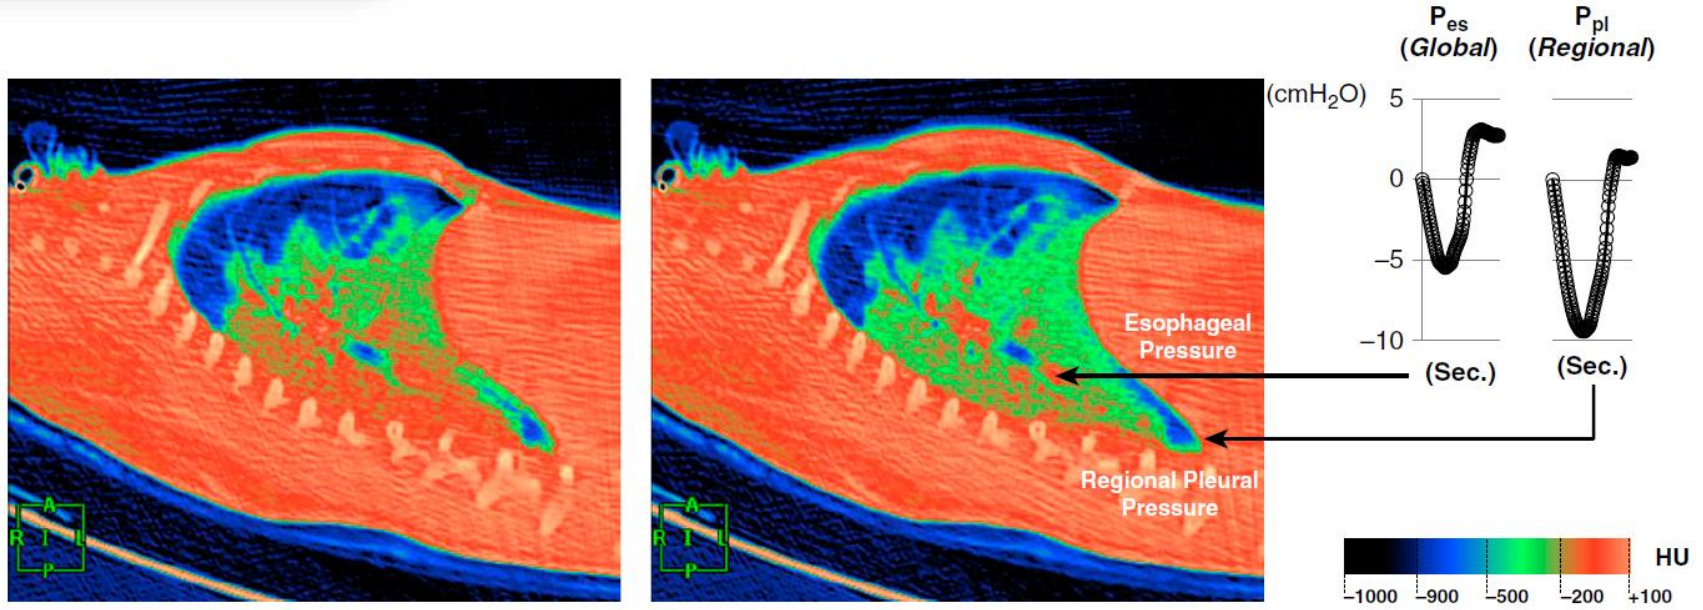

Figure 2. Spontaneous effort and distribution of regional ventilation and pleural pressure. Dynamic computed tomographic scan in end-expiration (*left*) demonstrates that the aerated lung (*blue*) is nondependent, while the dependent lung is densely atelectatic (*red*). At end-inspiration during a spontaneous breath (*middle*), there is little change in the nondependent aerated lung (*blue*); the dependent lung, previously densely atelectatic (*red*), is now partially aerated (*green/red*) (i.e., tidal recruitment). The inspiratory pleural pressure traces (*right*), measured at the *arrow tips*, show the negative deflections ("swings") in regional Ppl and global Pes during inspiration. However, the "swing" in regional Ppl is greater (by twofold) than the "swing" in Pes, indicating that diaphragm contraction results in greater distending pressure applied to the regional lung near the diaphragm, compared with the pressure transmitted to the remainder of the lung (i.e., Pes). A = anterior; HU = Hounsfield units; I = inferior; L = left; P = posterior; Pes = esophageal pressure; Ppl = pleural pressure; R = right.

Noninvasive Ventilation for patients with Hypoxemic ARF

Gemelli

Massive numbers of clinicians have been infected during the COVID-19 outbreak, which has raised **concerns around implementing aerosol-generating procedures**. Consequently, there appears to be a trend to avoid HFNC.

The scientific evidence of generation and dispersion of bio-aerosols via HFNC summarised here shows a similar risk to standard oxygen masks

Oxygen device	Flow rate L·min^{-1}	Dispersion distance cm
HFNC	60	17.2±3.3
	30	13.0±1.1
	10	6.5±1.5
Simple mask	15	11.2±0.7
	10	9.5±0.6
Non-rebreathing mask	10	24.6±2.2
Venturi mask at F_{IO_2} 0.4	6	39.7±1.6
Venturi mask at F_{IO_2} 0.35	6	27.2±1.1

Preliminary Findings on Control of Dispersion of Aerosols and Droplets During High-Velocity Nasal Insufflation Therapy Using a Simple Surgical Mask

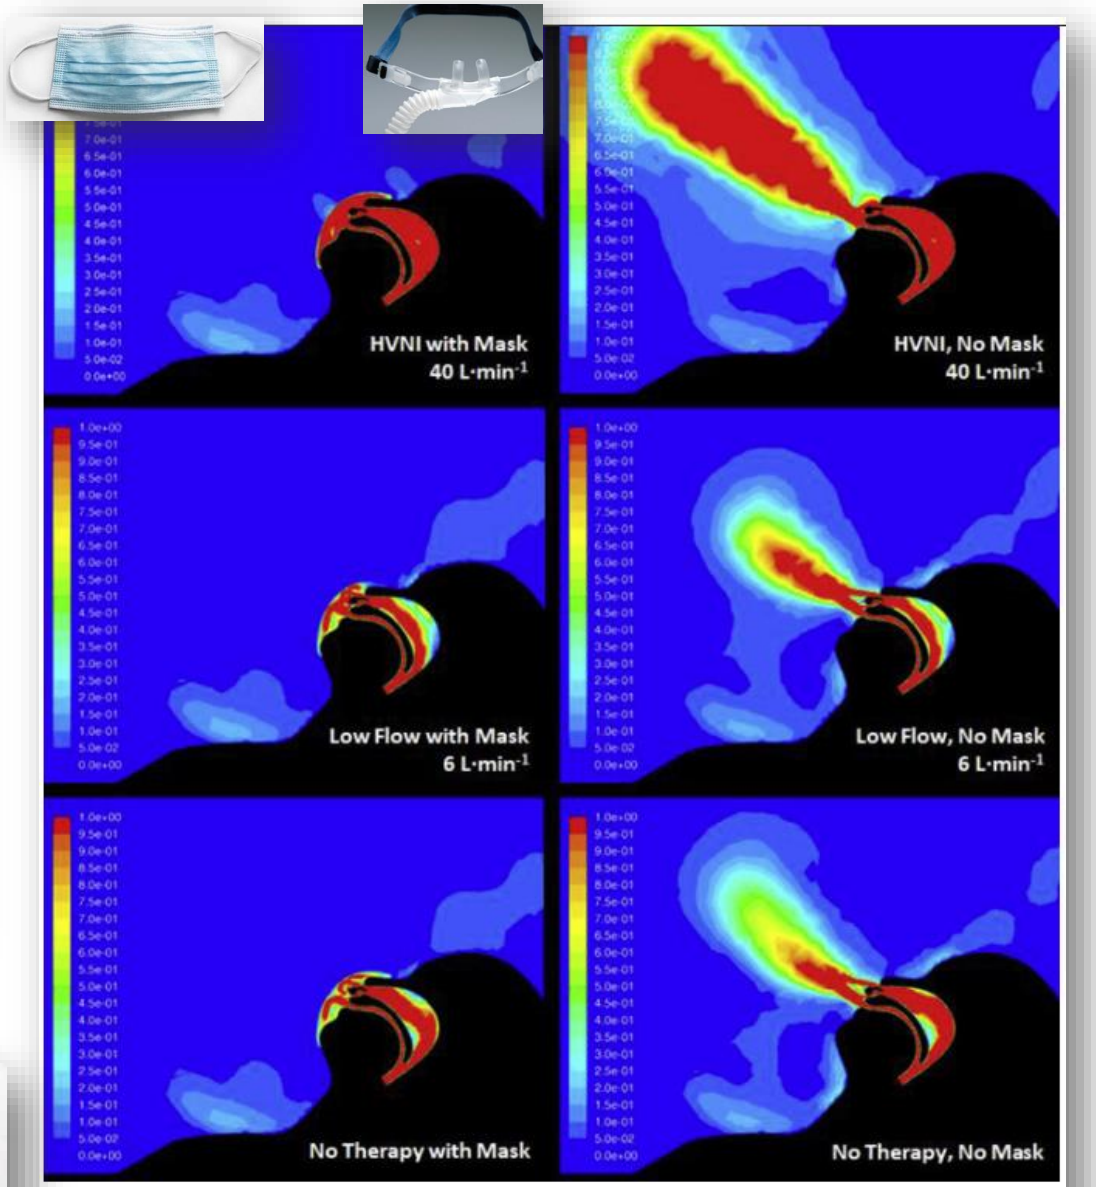
Implications for the High-Flow Nasal Cannula

Check for updates

To the Editor:

Coronavirus disease 2019 (COVID-19) pneumonia presents with severe hypoxemic respiratory failure, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The primary mode of transmission appears to be droplet-borne. Respiratory support and high levels of oxygen are required in the acute treatment of these patients. High-flow therapies have been included as part of the possible management of COVID-19.[1,2] One such modality is high-flow therapy, including high-velocity nasal insufflation (HVNI), high-flow nasal oxygen (HFNO), and high-flow nasal cannulation (HFNC). HVNI shares characteristics with HFNC/HFNO, in that all reliably deliver high flows of oxygen-enriched gas at high F_{IO_2} to the patient via an open nasal interface. High-flow therapy has demonstrated the ability to help manage hypoxic or type I respiratory failure.[3,4] All high-flow therapies also share the same issue of potential aerosol generation.

Recent correspondence has raised questions about health-care worker safety during the use of noninvasive ventilation and HFNC therapies.[5] HFNC has been studied and found to have limited particle dispersion when the cannula is properly fitted.[6] A recent recommendation has advised the use of a surgical mask over the face of the patient while wearing the high-flow therapy device to help reduce inadvertent aerosol.[7] This is the initial report of a study using computational fluid dynamic (CFD) simulation to determine the ability of a mask to reduce the velocity of exhaled gas flow and capture particles during HVNI.



Download : Download high-res image (714KB)

Download : Download full-size image

Figure 1. Velocity map of gas flow for all tested settings. HVNI= high-velocity nasal insufflation

The addition of a simple type I surgical mask may provide an effective tool to further reduce droplet deposition due to exhaled gas flow, except at mask leaks

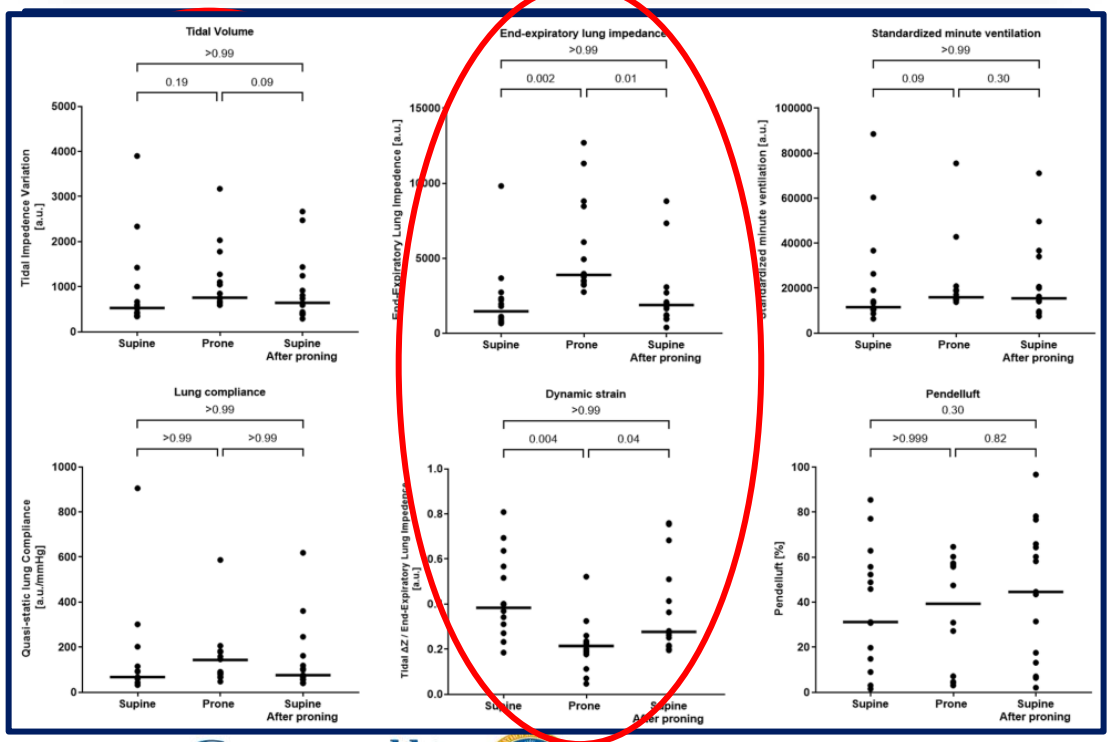
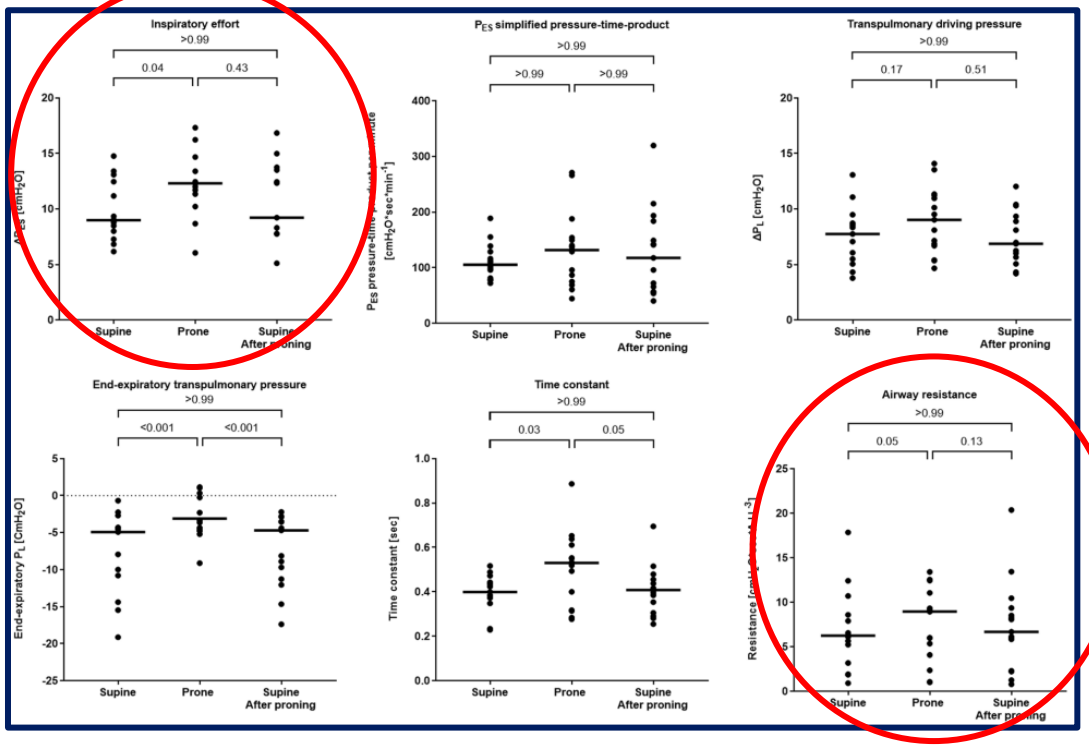
Menga[1,2], Tommaso Rosà[1,2], Teresa Michi[1,2], Gianmarco Lombardi[1,2], Melania Cesarano[1,2], Valentina Giammatteo[1,2], Giuseppe Bello[1,2], Simone Carelli[1,2], Salvatore L. Cutuli[1,2], Claudio Sandroni[1,2], Gennaro De Pascale[1,2], Antonio Pesenti[3], Salvatore M. Maggiore[4,5] and Massimo Antonelli[1,2]

Lo strain dinamico è il principale responsabile del VILI, ma ΔPes e pendelluft sono i prinicipali determinanti dello P-SILI!





Modifiche gravitazionali sulle piccole vie aeree, rotazione laterale del collo

Personalized noninvasive respiratory support for acute hypoxemic respiratory failure

Domenico Luca Grieco[1,2*], Laveena Munshi[3,4] and Lise Piquilloud[5]

Probabilmente non esiste una strategia perfetta per tutti i pazienti:

Individualizzazione!

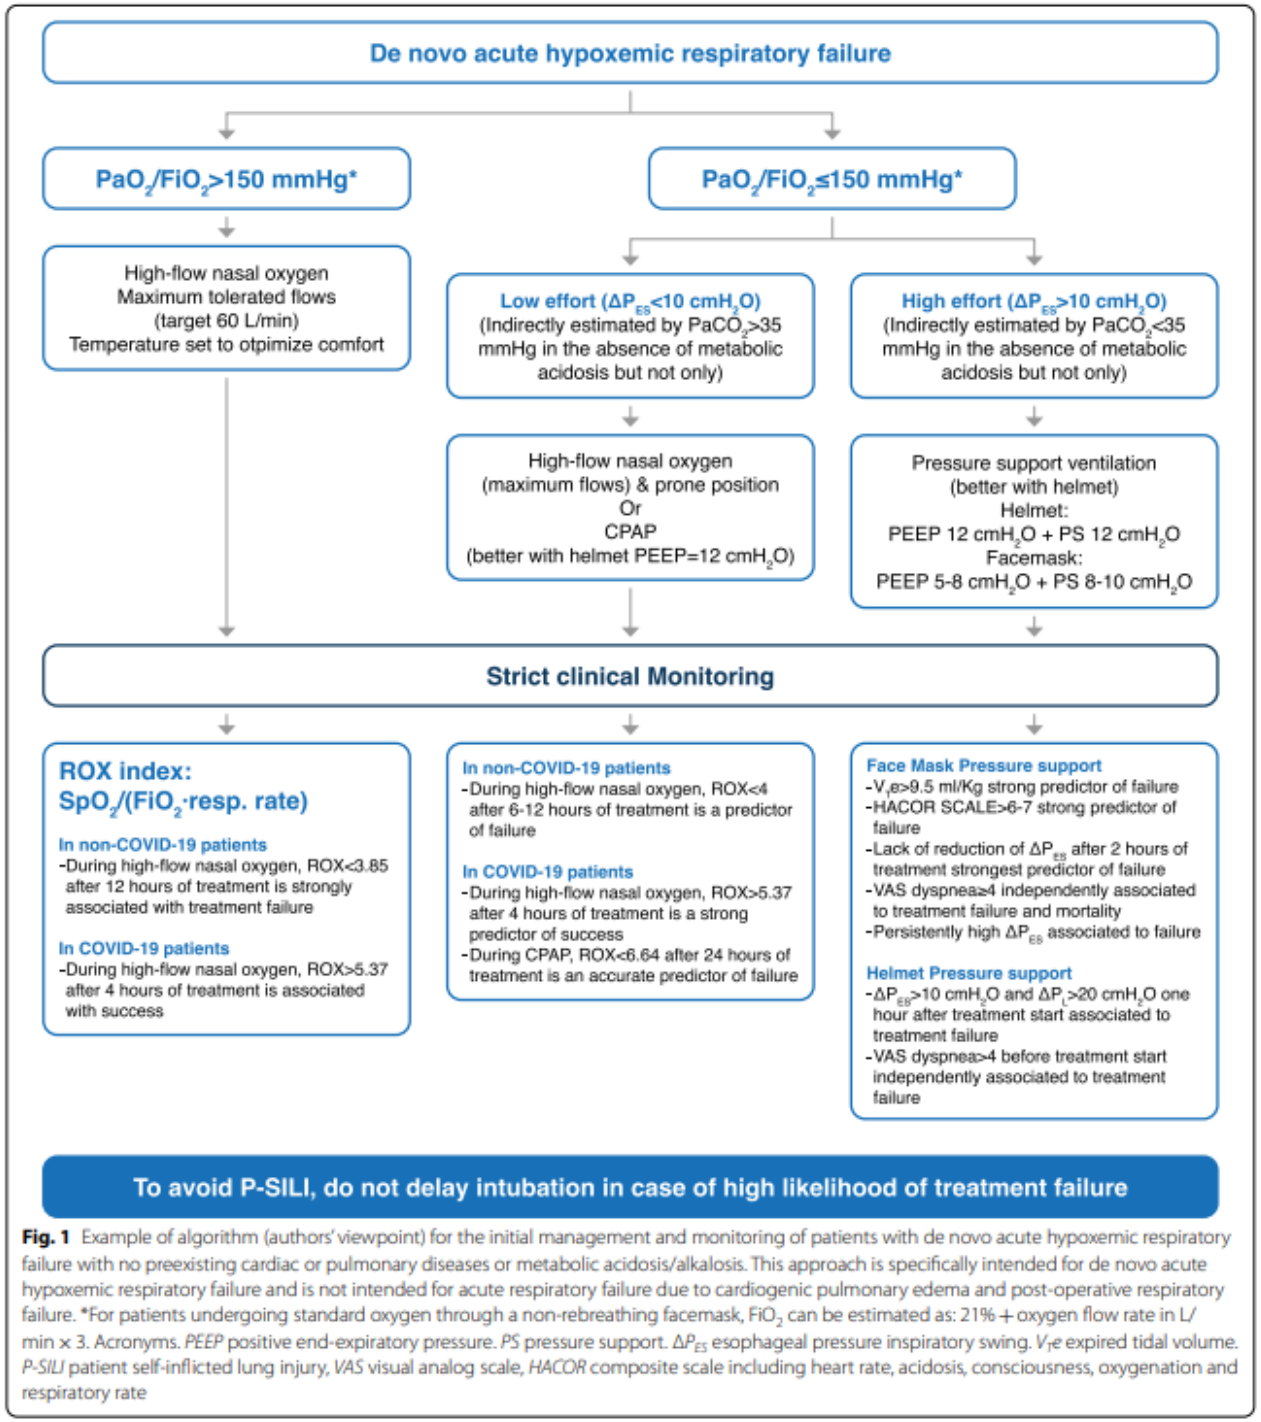

Fig. 1 Example of algorithm (authors' viewpoint) for the initial management and monitoring of patients with de novo acute hypoxemic respiratory failure with no preexisting cardiac or pulmonary diseases or metabolic acidosis/alkalosis. This approach is specifically intended for de novo acute hypoxemic respiratory failure and is not intended for acute respiratory failure due to cardiogenic pulmonary edema and post-operative respiratory failure. *For patients undergoing standard oxygen through a non-rebreathing facemask, FiO_2 can be estimated as: 21% + oxygen flow rate in L/min × 3. Acronyms. *PEEP* positive end-expiratory pressure. *PS* pressure support. ΔP_{ES} esophageal pressure inspiratory swing. V_Te expired tidal volume. *P-SILI* patient self-inflicted lung injury, *VAS* visual analog scale, *HACOR* composite scale including heart rate, acidosis, consciousness, oxygenation and respiratory rate
